**Abstract** The aims of this study were to evaluate the effects of both noncircular (ROT) and conventional (CON) chainring systems on aerobic and anaerobic cycling performances of professional cyclists, while analyzing the influence of varying the crank angle of maximum crank arm length of ROT. Fifteen professional road cyclists performed both incremental and sub-maximal aerobic tests and the Wingate anaerobic test in the laboratory. There were no statistical differences between CON and ROT in the aerobic tests, even when the best ROT position (ROT+) was selected. However, in the anaerobic test, maximal (4.2–9.1%) and mean (0.7–4.7%) power outputs were higher in ROT ( $P < 0.05$ ). These differences were greater when the ROT+ was selected (11.2 and 7.0%, respectively). Our findings suggest that ROT is able to improve anaerobic but not aerobic cycling performance in professional cyclists. Nevertheless, it must be adapted to each cyclist to ensure these improvements.

## Introduction

Performance in cyclists depends on several factors and recent studies have indicated that biomechanical alterations would also improve performance (Faria et al. 2005b; García-López et al. 2008). During cycling exercise, the force applied to the pedal is not constant along the crank revolution (Faria 1992; Kautz and Hull 1993), this being higher during downstroke (i.e., 0–180°, 0° crank angle is defined as top dead center) than upstroke (i.e., 180–360°). Moreover, the effective force is at its minimum when the crank is vertically positioned at both 0° (top dead center) and 180° (bottom dead center) (Fregly and Zajac 1996; Neptune and Herzog 2000), consequently, these positions are known as “dead points”. For these reasons, a biomechanical strategy to improve cycling performance has been to design noncircular chainrings (Hull et al. 1992) to change these patterns of pedal forces.

The theoretical benefits of these noncircular chainrings are: (1) to eliminate the dead spots (Santalla et al. 2002; Lucía et al. 2004), (2) to increase the crank arm length during the downstroke (Hue et al. 2001; Zamparo et al. 2002) and (3) to slow down the downstroke and accelerate the upstroke (Hull et al. 1992; Martin et al. 2002). Therefore, these chainrings allow highest torques during the crank revolution, mainly during the downstroke. However, none of them allowed varying the crank angle of maximum crank arm length.

When comparing conventional parameters of aerobic cycling performance (e.g.,  $VO_{2max}$ , anaerobic threshold, cycling efficiency, economy), previous studies reported no

differences between noncircular and circular chainrings (Hull et al. 1992; Cullen et al. 1992; Hue et al. 2001; Ratel et al. 2004; Lucía et al. 2004). Few studies reported advantages (Zamparo et al. 2002; Santalla et al. 2002) or disadvantages (Belen et al. 2007a) when the noncircular chainrings were used. Nevertheless, none of these studies has been carried out with professional road cyclists. Two previous studies used a new noncircular chainring [i.e., the Rotor Pedaling System (ROT)], and showed slight increases in cycling efficiency ( $\sim 3\%$ ) when ROT was used by physical education students (Santalla et al. 2002). However, they did not find differences when analyzing trained cyclists (Lucía et al. 2004). Additionally, these ROT models did not allow varying the crank angle of maximum crank arm length.

To the best of our knowledge, only five studies have investigated the effects of noncircular chainrings on anaerobic cycling performance (e.g., all-out tests) compared with conventional chainrings (CON). Martin et al. (2002) found increases in maximal single-leg cycling power when using a noncircular chainring, which supported the previous results obtained by Hue et al. (2001), showing an improvement in an all-out 1-km laboratory test. Hue et al. (2008) have also found improvements during a laboratory force–velocity test. However, in two recent studies no positive improvement was demonstrated using noncircular chainring in an all-out 1-km track cycling test (Belen et al. 2007b; Hue et al. 2007). To date, however, there are no empirical studies assessing the effects of noncircular chainrings on anaerobic cycling performance in professional cyclists.

Therefore, the aim of this study was to assess the effects of ROT compared with CON in professional cyclists performing both aerobic (i.e., maximal incremental and sub-maximal tests) and anaerobic tests (i.e., Wingate test). In addition, we analyzed the influence of varying the crank angle of maximum crank arm length of ROT (during the downstroke) on both tests.

## Methods

### Participants

Fifteen professional road cyclists ( $24 \pm 1$  year,  $69.5 \pm 1.4$  kg and  $1.77 \pm 0.02$  m) participated in this study. All of them were healthy male competitors of a continental cycling team with several years cycling experience. They had never used ROT before participating in this study. The evaluation protocol was designed according to the Helsinki Conference for research on human beings, and all cyclists signed informed consent before starting the study. The study Protocol was approved by the University of Leon Ethical Committee (Spain).

### The Rotor System

The Rotor System (ROT) is a pedal crank system configuration approved by the International Cycling Union. The ROT crank arms are not fixed at  $180^\circ$  and this eliminates the dead spots that occur with the conventional system (CON) at top-bottom dead centers (Fig. 1a). An extensive explanation of these specific characteristics was reported by Santalla et al. (2002) and Lucía et al. (2004). Another ROT characteristic is that the chainring rotation axis and the crank rotation axis do not coincide (Fig. 1b). The ROT model used in this study (Rotor-RCK, Rotor Bikes Components, Madrid, Spain) allowed varying the crank angle of maximum crank arm length between  $116^\circ$  (ROT-1),  $122^\circ$  (ROT-2),  $128^\circ$  (ROT-3) and  $134^\circ$  (ROT-4), where  $0^\circ$  is the crank placed at top dead center. This is an important difference in relation to previous studies on ROT, where only one position of crank angle of maximum crank arm length was tested (Santalla et al. 2002; Lucía et al. 2004). The adjustment of ROT is possible by rotating the chainring around the crank axis (Fig. 1b), and this produces a sinusoidal variation in relative angular velocity of the crank as

**Fig. 1** a The Rotor System used (Rotor-RCK). b Enlarged image of the chainring rotation axis (dotted line) and the crank rotation axis (solid line). The Rotor-RCK allows using four positions of crank angle of maximum crank arm length:  $116^\circ$  (ROT-1),  $122^\circ$  (ROT-2),  $128^\circ$  (ROT-3) and  $134^\circ$  (ROT-4)

**Fig. 2** The theoretical functioning of the Rotor System used in this study (Rotor-RCK). Relative crank angular velocity for a constant chain speed of the CON (solid line), ROT-1 and ROT-4 (dotted lines) within a crank revolution (0–360°)

a function of crank angle for a constant chain speed (Fig. 2). Figure 2 expresses a theoretical functioning because the cyclists did not pedal with a constant chain speed, but could be a good approximation to explain how ROT works. Therefore, it could be considered that the relative angular velocity of the crank is lower when the relative crank arm length is higher, and vice versa. By considering that ROT-1 to ROT-4 allows increasing the crank arm length during the downstroke, ROT could slow down the downstroke and accelerate the upstroke.

### Experimental design

At the beginning of the preparation period (December) the cyclists were evaluated in five separate testing sessions (days 1–5) with a recovery period of 48 h between testing sessions. On days 1 and 2 the cyclists underwent two incremental tests, on day 3 the cyclists carried out a sub-maximal test, and on days 4 and 5 the cyclists performed various maximal intensity tests (one force–velocity test and five Wingate anaerobic tests). All the testing sessions were performed at the same time of the day (in the morning, between 08:00 and 13:00 h), under similar environmental conditions (20–25°C, 60 to 65% relative humidity). Each test was preceded by a 10-min warm-up period at a power output of 100 W with 5 min separating the end of the warm-up from the testing. The lengths of the crank arms were adapted for all subjects during all tests, and clip-on pedals were used. The incremental and sub-maximal tests were performed on a cyclosimulator (Cateye CS-1000, Cateye Co. Ltd, Osaka, Japan) with the subjects using their own competition cycles, because this could eliminate the problem of the cyclists not being able to configure the cycle to their normal riding posture (Faria et al. 2005a) and has been used in previous studies dealing with noncircular chainrings (Santalla et al. 2002).

The maximal anaerobic tests (i.e., force–velocity and Wingate) were performed on a mechanically braked cycle ergometer (Monark 818E, Monark Exercise AB, Varberg, Sweden), because it has been recognized as a valid and reliable method of anaerobic exercise testing (Micklewright et al. 2006) and has been used in previous research dealing with noncircular chainrings (Hue et al. 2008). The tyre pressure (8 atm) was the same for all subjects during the tests on the cyclosimulator. All the cyclists performed no more than a light training session the day before the testing sessions.

### Incremental test

The cyclists underwent two continuous and progressive maximal oxygen uptake tests to exhaustion, in which they used CON and ROT with the crank angle of maximum crank arm length at 128° (ROT-3), the order of the tests being randomized. The cyclists chose their preferred gear ratio during the first test; in the second test they were required to use the same gear ratio for each speed. The tests started at 32 km h<sup>-1</sup> and the bicycle speed was increased by 1 km h<sup>-1</sup> every 1 min to exhaustion (Rodríguez-Marroyo et al. 2003), with continuous electrocardiograph (Schiller AG, Baar, Switzerland) and breath-by-breath respiration gas analysis during the whole effort (Medical Graphics System CPX-Plus, Medical Graphics Corporation, St Paul, MN). Heart rate and pedal cadence were monitored telemetrically during the whole duration of the test (Polar Xtrainer Plus, Polar Electro Oy, Kempele, Finland), and the power output was analyzed with a valid and reliable powermeter for pedaling intensities of between 100 and 450 W (PowerTap, CycleOps, Madison, USA) (Bertucci et al. 2005). The other variables obtained in the test were: oxygen consumption, ventilation, ventilatory equivalents for oxygen and carbon dioxide, and the respiratory exchange ratio. All these variables were averaged for each 10-s period.  $VO_{2max}$  and maximal power output were recorded as the highest values obtained for the last 10-s period before exhaustion (Hue et al. 2001). The ventilatory threshold and the respiratory compensation threshold were identified according to Davis's (1985) criteria.

### Sub-maximal test

The cyclists performed one sub-maximal test consisting of five sets of 10 min on the cyclosimulator with ROT-1, ROT-2, ROT-3, ROT-4 and CON, the order of the sets also being randomized. The power output for the sub-maximal test was set at a value equivalent to 90% of the power at respiratory compensation threshold during the incremental test with CON ( $\sim 75\% VO_{2max}$ ). We selected this power output because: (1) the cyclists did not reach their optimal

performance in the pre-season period, and it is difficult to sustain the power output at the respiratory compensation threshold for a long period, (2) the respiratory exchange ratio at 90% of the respiratory compensation threshold was lower than 1.00 in all the cyclists studied. They maintained this power output during 5 sets of 10-min effort period with 15-min recovery in between. The recovery period was used to change and/or to adjust the chainring system. The cyclists were able to drink 100 ml of water during the recovery periods of each test to avoid dehydration. The cyclists selected their preferred gear ratio and cadence during the first set and were required to use the same configuration during the successive sets. Likewise, to eliminate the metabolic cost impact of modifying the cyclists' position during sub-maximal test (Heil et al. 1997), the cyclists used the same posture (i.e., upright sitting position). Heart rate, power output, oxygen consumption, and respiratory exchange ratio were monitored during the entire duration of the test, and were averaged for the last 2 min of each 10-min set. Gross mechanical efficiency was calculated as the ratio of work accomplished (expressed in  $\text{kcal min}^{-1}$ ) to energy expended ( $\text{kcal min}^{-1}$ ) (Coyle et al. 1992; Sidossis et al. 1992), using the tables of Westenskow (1988) for the corresponding energy equivalent for each oxygen consumption value based on respiratory exchange ratio. Cycling economy was calculated as the work accomplished per litre of oxygen consumed, and was expressed in  $\text{kJ l}^{-1}$  (Moseley et al. 2004). The best ROT (ROT+) was obtained for each cyclist from the positions ROT-1, ROT-2, ROT-3 or ROT-4, by selecting the set with higher values of gross mechanical efficiency.

#### Wingate and force–velocity anaerobic tests

The cyclists performed a force–velocity test and two Wingate anaerobic tests on day 4, and three Wingate anaerobic tests on day 5, with  $\sim 60$  min of recovery in between. The cycle ergometer was adapted to the characteristics of the cyclists' bicycles, and was fixed on the ground to avoid displacement. It was equipped with two 172.5-mm crank arms, a gear ratio of 6.12 m (flywheel revolutions per pedal crank revolution) and a handlebar and a saddle similar to those used by the cyclists. To record the right crank velocity, four magnetic sensors were placed at 90°, 180°, 270° and 360° crank angle. These sensors were connected to special software (SportSpeed, University of Leon, Spain) validated in a previous study for an accuracy of 500 Hz (Garcia-Lopez et al. 2005).

The cyclists performed a force–velocity test with CON to obtain the optimal braking force (Vandewalle et al. 1987). It consisted of performing a series of short maximal sprints ( $\sim 6$  s) followed by a 5-min rest. The initial braking

force was 20 N, and was increased by 20 N in each sprint until the subjects were unable to reach a peak crank velocity higher than 100 rpm. The optimal braking force was obtained from the relation between force and power by using a third order polynomial function (Arsac et al. 1996). We used this optimal braking force for the five Wingate anaerobic tests, approaching  $\sim 0.112$  kp per kg of body mass.

The order of the Wingate anaerobic tests was randomized in the same way as the sub-maximal tests for the ROT and CON devices. These consisted of pedaling at maximal speed for 30 s against the optimal breaking force obtained in the force–velocity test. The cyclists remained seated on the saddle and they were vigorously encouraged to reach the maximum cadence as soon as possible. In each test, power output was corrected for inertial effects of the flywheel (Lakomy 1986). The variables obtained in the test were: peak power output, mean power output, minimum power output, maximal pedaling rate, time to peak power output, and fatigue rate according to the following equation (Micklewright et al. 2006):

$$\text{FR}(\text{W s}^{-1}) = (P_{\text{peak}} - P_{\text{mean}}) \times (30 - \text{TP}_{\text{peak}})^{-1}$$

where FR is the fatigue rate in  $\text{W s}^{-1}$ ,  $P_{\text{peak}}$  is the peak power output in W,  $P_{\text{mean}}$  is the mean power output in W, and the  $\text{TP}_{\text{peak}}$  is the time to the  $P_{\text{peak}}$  in s. ROT+ was obtained by selecting the higher values of mean power output of each cyclist with any of the ROT positions.

#### Statistical analysis

The results are expressed as mean and the standard error of the mean. Statistical analysis was carried out using SPSS + version 13.0 (Chicago, IL, USA). The Kolmogorov–Smirnov test was applied to ensure a Gaussian distribution of the results. The analyzed variables during the incremental tests (CON and ROT-3) were compared using Student's paired *t* test. The variables of the sub-maximal and Wingate anaerobic tests (CON, ROT-1, ROT-2, ROT-3 and ROT-4) were compared using an analysis of variance (ANOVA) with repeated measures. Newman–Keuls post hoc analysis was used to establish statistical differences between means. Statistical significance was set at  $P < 0.05$ .

## Results

#### Incremental test

No statistical differences were found between CON and ROT-3 in the incremental test (Table 1).

**Table 1** Maximal, respiratory compensation threshold (RCT) and ventilatory threshold (VT) values (mean  $\pm$  SEM) during the incremental test

CON conventional pedaling system, ROT-3 rotor pedaling systems

#### Sub-maximal test

No statistical differences were found between CON and ROT in the sub-maximal test (Table 2), independently of the crank angle of maximum crank arm length with ROT (i.e., ROT-1, ROT-2, ROT-3 or ROT-4). Furthermore, we did not find any difference when ROT+ and CON were compared.

#### Wingate anaerobic test

Both peak (4.2–9.1%) and mean (0.7–4.7%) power outputs with ROT were always greater than CON (Table 3). However, these differences were only statistically significant when comparing the peak power output in ROT-3 and ROT-4, and the mean power output in ROT-4. The maximal

pedaling rate was greater with ROT-4 than CON ( $P < 0.05$ ). Both peak (11.2%) and mean (7.0%) power outputs were higher with ROT+ than CON ( $P < 0.05$ ), whereas the time to peak power output was lower with ROT+ than CON ( $P < 0.05$ ), and no statistical differences were found for the fatigue rate. Power output was higher with ROT+ than CON ( $P < 0.05$ ) during the first 25 s (Fig. 3).

#### Discussion

The main finding of our study was that Rotor System (ROT) is able to improve the anaerobic performance during the Wingate anaerobic test, but seems not to be able to improve either aerobic power (measured via the VO<sub>2max</sub>) or aerobic cycling efficiency (measured via the gross mechanical efficiency and the cycling economy) in professional cyclists when compared to CON.

We hypothesized that ROT's mechanical characteristics (Figs. 1, 2) possibly improved the performance during the Wingate anaerobic test (Table 3; Fig. 3), because ROT allowed varying the length of a crank arm of 175 mm between 205.8 mm (crank angle of maximum crank arm length) and 147.6 mm (crank angle of minimum crank arm length). This variation of crank arm length probably allowed a higher force/power production during the downstroke and a lower negative momentum (negative force  $\times$  distance) during the upstroke (Neptune and Herzog 2000; Sanderson et al. 2000). Some studies used this same strategy and also observed improvements during several anaerobic tests (Hue et al. 2001). For example, Hue and colleagues varied 25 mm the crank arm length and showed improvements between  $\sim 7\%$  (Hue et al. 2001) and  $\sim 10\%$  (Hue et al. 2008). Martin et al. (2002) varied the crank arm length by 20 mm and showed greater power (between 4–8%). These improvements were similar to those obtained in the present study with ROT (4–9%, Table 3). Nevertheless, another study (Belen et al. 2007b) did not show statistical differences between circular and noncircular chainrings during an anaerobic test, possibly because they used an inverse strategy, and the crank arm

length decreased 10 mm at 90° and increased 10 mm at 270°. This could produce an opposite effect to the one described in the previous paragraph, not allowing an improvement in the anaerobic cycling performance.

During the Wingate anaerobic test the pedal cadence (123–129 rpm, Table 3) was in an optimum range (110–140 rpm) to obtain the maximal power output (Samozino et al. 2007; Martin et al. 2007). Sixty-eight percent of the cyclists obtained ROT+ by using ROT-4, and the 25, 5 and 2% of them by using ROT-3, ROT-2 and ROT-1, respectively. Consequently, mean and peak power outputs were higher in ROT-3 and ROT-4 than in CON (Table 3). According to these results, we can hypothesize that non-circular chainrings need to be adapted to each cyclist to improve anaerobic performance. This could be due to: (1) by considering the theoretical functioning of ROT (Fig. 2), unlike ROT-1 and ROT-2, ROT-3 and ROT-4 could shorten the time the cranks are at the top dead center (0°), because the relative crank angular velocity could be higher. However, future studies with ROT should evaluate the adjustment between its theoretical and practical

functioning (crank angular kinematics). (2) Also, ROT-3 and ROT-4 clearly introduce the crank angle of maximum crank arm length after 120° (128° and 134°, respectively). This could maximize the contribution of the non-muscular component of the pedal reaction force, it being higher than the muscular component at high cadences (Neptune and Herzog 1999), and increasing its maximum magnitude to crank angles higher than 120° at 105–120 rpm (Kautz and Hull 1993). Nevertheless, future studies with ROT should confirm this last hypothesis by performing a kinetic analysis. It is important to note that the ROT used in this study is the only model of noncircular chainring that allows varying the crank angle of maximum crank arm length, and setting it above 120°.

Some studies consider that performing the anaerobic test in the laboratory (e.g., Wingate anaerobic test) or in the field (e.g., 1-km all-out in velodrome) could affect the results, because in the laboratory the cyclists do not usually use their bicycles (Hull et al. 1992), the ergometers do not usually oscillate from side to side (Bertucci et al. 2005), and aerodynamic drag does not exist (Martin et al. 2007). Nevertheless, Gardner et al. (2007) did not find differences between velodrome and laboratory results of seven elite track cyclists, and speculated about the possible influence of skill performance to produce similar power during laboratory and field trials. This hypothesis deserves further study, and future field studies should examine whether the Rotor System could improve performance in short track cycling competitions (e.g., 200-m sprint). We obtained a lower maximal power output with CON ( $\sim 14$  W kg<sup>-1</sup>, Table 3) than the cyclists studied by Calbet et al. (2003) (between 17–21 W kg<sup>-1</sup>) who used the same ergometer as in the present study, possibly because our subjects were race cyclists and not track cyclists.

We did not find statistical differences between ROT and CON during the incremental (Table 1) and sub-maximal

tests (Table 2). These results coincided with the majority of previous studies that compared circular and noncircular chainrings during incremental tests (Henderson et al. 1977; Santalla et al. 2002; Lucía et al. 2004; Ratel et al. 2004) and sub-maximal tests (Cullen et al. 1992; Hull et al. 1992; Ratel et al. 2004; Lucía et al. 2004). Contrary to these findings, other previous studies with ROT seemed to exhibit higher delta mechanical efficiency at 60–90%  $VO_{2max}$  during an incremental test (Santalla et al. 2002), but follow-up testing failed to confirm these results (Lucía et al. 2004). Zamparo et al. (2002) obtained a small improvement (1.3–1.8%) with a noncircular chainring at 250–300 W, but they evaluated seven non-professional road cyclists who pedalled at 60 rpm, and only four and the two cyclists were able to pedal aerobically (respiratory exchange ratio lower than 1.00) up to 250 and 300 W, respectively. Only one study showed lower performance with a peculiar noncircular chainring (Belen et al. 2007a), which decreased and increased the crank arm length by 25 mm at 90° and 270°, respectively; they also evaluated physical education students who had little experience of cycling, and all of them used the same bicycle. According to our results and those of the majority of previous studies, we can hypothesize that noncircular chainrings do not improve aerobic performance during prolonged pedaling exercise. This could be due to: (1) *different theoretical and practical functioning of noncircular chainrings (crank angular kinematics)*, because most of the optimization analyses of cycling performance were aimed at maximizing short-term power production and not cycling efficiency (Hull et al. 1992). Therefore, future studies with ROT should evaluate the adjustment between its theoretical (Fig. 2) and practical functioning; (2) *the inclusion of additional parts which imply supplementary weight and friction* (Belen et al. 2007a), because Rotor-RCK weighs ~350 g more than CON and has a shorter stopping time after rotating; (3) *the cycling experience* (Lucía et al. 2004), because the well-trained cyclists could not use the theoretical biomechanical advantage brought about by ROT.

The cyclists who participated in the present study had not used ROT previously, and this could condition our results. Nevertheless, Lucía et al. (2004) compared the cycling mechanical efficiency of five cyclists who used ROT for 8–9 months and five cyclists who had not used ROT previously and there were no significant differences between these two groups. Furthermore, a study by Neptune and Herzog (2000) showed that the adaptation to the subjects' muscle coordination occurred within the first 10–20 cycles after switching to the noncircular chainring. However, it could be that the positive effects of noncircular chainrings during aerobic cycling exercise could be effective in subjects training with, and only with, these

chainrings for long time (i.e., several years). Future longitudinal studies with more subjects and more time of training than Lucía et al. (2004) are necessary to elucidate this question.

In conclusion, ROT is able to improve anaerobic performance during the Wingate test but not aerobic power (measured during an incremental test) or aerobic response (elicited during a sub-maximal test) in professional road cyclists when compared with CON. The improvement in the Wingate anaerobic test was in a range of 4–9%, similar to previous studies that used noncircular chainrings during various anaerobic tests. This could be due to: the elimination of dead points, variation in crank angular velocity, the individualization of the crank angle of maximum crank arm length, which could involve a short time with the cranks at top dead center, and a higher contribution of the non-muscular component during the downstroke. We suggest that the crank angle of maximum crank arm length must be adapted to each cyclist to improve anaerobic performance. Future studies should test if this ROT model (Rotor-RCK) improves anaerobic performance during a short field test. ROT did not improve aerobic power (incremental test) or cycling economy and gross mechanical efficiency (sub-maximal test), which could be due to: its higher weight (~350 g) and friction when compared with CON, and the influence of cycling experience, because we evaluated professional cyclists. Future studies with ROT should evaluate the adjustment between its theoretical and practical functioning (crank angular kinematics), its influence on the pattern of force application (pedal reaction forces), and also its longitudinal effects (several years of training) on the aerobic cycling performance.

**Acknowledgments** The authors would like to thank the professional road cyclists who participated in this study for their collaboration. This work has been supported by the Consejería de Educación y Cultura de la Junta de Castilla y León (Spain) and the Consejo Superior de Deportes. Ministerio de Educación, Cultura y Deporte, Spain (Grant 12/UPB10/07).
